Sommario

Traduzione dell'abstract in italiano.

1. Synopsis

Here goes the synopsis of your thesis. It consists of an introductory part followed by a description on the thesis content.

This thesis is organized as follows.

2. My chapter

2.1. Matrices

Assuming W'_i and V'_i for i = 1, ..., m full rank, define the following matrices:

$$X = \begin{bmatrix} W'_1 & V'_1 & 0 & \dots & 0 & 0 \\ W'_2 & 0 & V'_2 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ W'_{m-1} & 0 & 0 & \dots & V'_{m-1} & 0 \\ W'_m & 0 & 0 & \dots & 0 & V'_m \end{bmatrix}$$

with $X \in \mathbb{R}^{N \times (m-1)p+q}$, $H = X(X^TX)^{-1}X^T$ and $Q = I_N - H$, $\in \mathbb{R}^{N \times N}$, which are the matrixes that project a vector, respectively, onto the subspace spanned by the columns of X and onto its orthogonal complement with respect to \mathbb{R}^N . Notice that despite the matrix X^TX exhibits a pattern where only the first row, the first column and the diagonal are different from 0, the inverse of this type of matrix is usually dense (*might be interesting studying an incomplete factorization of this matrix though*).

The discrete problem leads to the solution of the following linear system of equations:

$$\begin{bmatrix} \tilde{\mathbf{Y}}^{\mathsf{T}} \mathbf{Q} \tilde{\mathbf{Y}} & -\lambda \tilde{\mathbf{R}}_{1} \\ -\lambda \tilde{\mathbf{R}}_{1} & -\lambda \tilde{\mathbf{R}}_{0} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{f}} \\ \hat{\mathbf{g}} \end{bmatrix} = \begin{bmatrix} \tilde{\mathbf{Y}}^{\mathsf{T}} \mathbf{Q} \mathbf{z} \\ 0 \end{bmatrix}$$
(2.1)

We call it monolithic because the number of units might be big and so the number of nodes for each unit. Therefore our aim is to avoid the solution of such high dimension linear system, in favour of splitting it into many systems of lower dimension. In case the dimensions of the monolithic system are treatable, the Woodbury decomposition formula, described in appendix A.1, can be used to speed up the computation of the solution for different values of λ . The decomposition is entirely analogous to the one described in the appendix, with

$$E = \begin{bmatrix} \tilde{\Psi}^{\mathsf{T}} \tilde{\Psi} & -\lambda \tilde{R}_{1} \\ -\lambda \tilde{R}_{1} & -\lambda \tilde{R}_{0} \end{bmatrix} \quad U = \begin{bmatrix} \tilde{\Psi}^{\mathsf{T}} X \\ 0 \end{bmatrix}$$

$$C = - \begin{bmatrix} (X^{\mathsf{T}} X)^{-1} \end{bmatrix} \quad V = U^{\mathsf{T}}$$
(2.2)

2.2. Iterative methods

Following the ideas stemmed from the spatio-temporal regression in Pollini and Ponti [PP13] and Massardi and Spaziani [MS21], we consider an iterative scheme. At each

step the scheme computes an approximate solution of the monolithic system by solving a single-unit problem for each statistical unit. The algorithm stops when one of the following criteria is met:

- A maximum number of iterations is reached;
- The functional of the estimated solution $J_{\Omega_i,\lambda}(\hat{f}^i)$ has reached stagnation, that is the relative increment $(J_{\Omega_i,\lambda}(\hat{f}^i)-J_{\Omega_i,\lambda}(\hat{f}^{i-1}))/J_{\Omega_i,\lambda}(\hat{f}^i)$ is below a certain threshold (in the code 10^{-4} was used);
- The estimated solution has reached stagnation, that is the relative increment $\|\hat{f}^i \hat{f}^{i-1}\| / \|\hat{f}^i\|$ is below a certain threshold (in the code 10^{-8} was used).

The details of a first possible implementation are described in the following section.

2.2.1. The block diagonal approach

Looking at the monolithic equation 2.1, the question of how to formulate an approximation of the term $\tilde{\Psi}^T Q \tilde{\Psi}$ naturally arises. In particular, a suitable block approximation allows to make the estimated field \hat{f}_i of statistical unit i independent from the observations in the other units, for every unit i.

To this purpose, the following approximation is first considered:

$$\tilde{\Psi}^{\mathsf{T}} Q \tilde{\Psi} = \begin{bmatrix} \Psi^{\mathsf{T}} Q_1 \Psi & 0 & \dots & 0 \\ 0 & \Psi^{\mathsf{T}} Q_2 \Psi & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \dots & 0 & \Psi^{\mathsf{T}} Q_m \Psi \end{bmatrix}$$
(2.3)

Here Q_i indicates the i-th diagonal block of Q of dimension $n \times n$. By definition of Q_i , it is equal to $I_n - X_i(X^TX)^{-1}X_i^T$, with $X_i = X((i-1)m+1:im,:)$, where the typical notation of the MATLAB language has been used to express a suitable submatrix. Another possible way to express the blocks $\Psi^TQ_i\Psi$ of matrix 2.3 is through Woodbury decomposition (appendix A.1) with a use analogous to the one in 2.2. In fact, $\Psi^TQ_i\Psi$ is the i-th block diagonal of matrix $\tilde{\Psi}^TQ\tilde{\Psi}$, which in turn can be expressed as $\tilde{\Psi}^T\tilde{\Psi}-\tilde{\Psi}^TH\tilde{\Psi}$. Thus, defining $U=\tilde{\Psi}^TX$, $C=-(X^TX)^{-1}$, $V=U^T$, matrix $\Psi^TQ_i\Psi$ can be expressed as $\Psi^T\Psi+U_iCV_i$, where $U_i=U((i-1)m+1:im,:)$, $V_i=U_i^T$.

2.2.2. Initialization

The inizialization consists in finding a good guess $(\hat{\mathbf{f}}^0, \hat{\mathbf{g}}^0)$ to start the algorithm from; for this purpose, the following m problems are solved: for i = 1, ..., m solve

$$\begin{bmatrix} \Psi^{\mathsf{T}} Q_{i} \Psi & -\lambda R_{1} \\ -\lambda R_{1} & -\lambda R_{0} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{f}}_{i}^{0} \\ \hat{\mathbf{g}}_{i}^{0} \end{bmatrix} = \begin{bmatrix} \mathbf{u}_{i} \\ 0 \end{bmatrix}$$
 (2.4)

where \mathbf{u}_i is the vector whose components are the first n components of $\tilde{\Psi}^T Q \mathbf{z}$ starting from the n(i-1)+1-th component.

2.2.3. Iterations

The idea behind the iterative scheme is, having a guess of a solution $(\hat{\mathbf{f}}^{k-1}, \hat{\mathbf{g}}^{k-1})$, to compute a new guess $(\hat{\mathbf{f}}^k, \hat{\mathbf{g}}^k)$ by replacing the mutual interaction of the system variables corresponding to different units with their contibution given by their previous value. For example, the first n equations of the monolithic system 2.1 read

$$\begin{bmatrix} \Psi^{\mathsf{T}} Q_{1,1} \Psi & \Psi^{\mathsf{T}} Q_{1,2} \Psi & \dots & \Psi^{\mathsf{T}} Q_{1,m} \Psi & -\lambda R_1 \end{bmatrix} \begin{bmatrix} \hat{\mathbf{f}}_1 \\ \hat{\mathbf{f}}_2 \\ \vdots \\ \hat{\mathbf{f}}_m \\ \hat{\mathbf{g}}_1 \end{bmatrix} = \begin{bmatrix} \mathbf{u}_1 \end{bmatrix}$$
(2.5)

where $Q_{i,j}$ indicates block of row i and column j of matrix Q. Substituting $\hat{\mathbf{f}}_j$ for $j=1,\ldots,m$ with $\hat{\mathbf{f}}_j^{k-1}$ and generalizing, the iterative scheme reads: for $i=1,\ldots,m$ solve

$$\begin{bmatrix} \Psi^{\mathsf{T}} Q_{i} \Psi & -\lambda R_{1} \\ -\lambda R_{1} & -\lambda R_{0} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{f}}_{i}^{k} \\ \hat{\mathbf{g}}_{i}^{k} \end{bmatrix} = \begin{bmatrix} \mathbf{r}_{i} \\ 0 \end{bmatrix}$$
 (2.6)

where

$$\mathbf{r}_{i} = \mathbf{u}_{i} - \sum_{\substack{j=1\\j\neq i}}^{m} \Psi^{\mathsf{T}} Q_{i,j} \Psi \hat{\mathbf{f}}_{j}^{k-1}$$
(2.7)

3. Simulation studies

Appendices

A. Formulae

A.1. Woodbury decomposition

The following matrix identity holds.

Proposition A.1 (Woodbury matrix identity). Let M be a square $m \times m$ matrix which can be written as the sum E + UCV, with E being $m \times m$, U being $m \times n$, C being a square $n \times n$ matrix, and $V n \times m$. Then

$$(E + UCV)^{-1} = E^{-1} - E^{-1}U(C^{-1} + VE^{-1}U)^{-1}VE^{-1}$$
 (A.1)

This equation is exploited for faster system solving in the fdaPDE library. In the simple space-only problem described *e.g.* in [San21], the presence of covariates leads to a linear system involving the following matrix M:

$$M = \begin{bmatrix} \Psi^{\mathsf{T}} Q \Psi & -\lambda R_1 \\ -\lambda R_1 & -\lambda R_0 \end{bmatrix}$$

Remembering that the projection matrix Q is defined as I - H, M can be split into the following two components, one independent from λ :

$$M = \begin{bmatrix} \Psi^{\mathsf{T}} \Psi & -\lambda R_1 \\ -\lambda R_1 & -\lambda R_0 \end{bmatrix} + \begin{bmatrix} -\Psi^{\mathsf{T}} H \Psi & 0 \\ 0 & 0 \end{bmatrix}$$

By calling E the matrix on the left (which is also the matrix corresponding to the problem without covariates), and remembering that $H = W(W^TW)^{-1}W^T$, Woodbury decomposition can be exploited defining the following matrices U, C, V:

$$\begin{bmatrix} -\Psi^{\mathsf{T}} W (W^{\mathsf{T}} W)^{-1} W^{\mathsf{T}} \Psi & 0 \\ 0 & 0 \end{bmatrix} = \mathsf{UCV}$$

$$\mathsf{U} = \begin{bmatrix} \Psi^{\mathsf{T}} W \\ 0 \end{bmatrix}$$

$$\mathsf{C} = - \begin{bmatrix} (W^{\mathsf{T}} W)^{-1} \end{bmatrix}$$

$$\mathsf{V} = \mathsf{U}^{\mathsf{T}} = \begin{bmatrix} W^{\mathsf{T}} \Psi & 0 \end{bmatrix}$$

where the 0s indicate matrices of zeros of suitable dimensions.

In this way, when computing the solution of the system for different values of λ , only the factorization of the matrix E will have to be computed.
